

# One- and Two-Level Filter-Bank Convolvers

See-May Phoong, *Student Member, IEEE*, and P. P. Vaidyanathan, *Fellow, IEEE*

**Abstract**—In a recent paper, it was shown in detail that in the case of orthonormal and biorthogonal filter banks we can convolve two signals by directly convolving the subband signals and combining the results. In this paper, we further generalize the result. We also derive the *statistical* coding gain for the generalized subband convolver. As an application, we derive a novel low sensitivity structure for FIR filters from the convolution theorem. We define and derive a *deterministic* coding gain of the subband convolver over direct convolution for a fixed wordlength implementation. This gain serves as a figure of merit for the low sensitivity structure. Several numerical examples are included to demonstrate the usefulness of these ideas. By using the generalized polyphase representation, we show that the subband convolvers, linear periodically time varying systems, and digital block filtering can be viewed in a unified manner. Furthermore, the scheme called IFIR filtering is shown to be a special case of the convolver.

## I. INTRODUCTION

### A. Main Results of this Paper and Previous Work

CONVOLUTION plays a central role in digital signal processing. Many well-known algorithms are proposed to reduce the computational complexity of convolution [1]. In this paper, our aim is not to find an algorithm that is faster than existing fast algorithms. Our goal is to find a more accurate way to compute the convolution when the convolution is implemented with finite precision. For this we use filter bank techniques. Consider the filter bank in Fig. 1(a), where  $H_k(z)$  are the analysis filters and  $F_k(z)$  are the synthesis filters. This multirate system has been studied by a number of researchers [2]–[8]. The analysis bank  $\{H_k(z)\}$  splits the signal  $x(n)$  into the subband signals  $x_k(n)$ .

In a recent paper [2], it was shown that if the systems in Fig. 1 are perfect reconstruction systems (i.e.,  $x(n) = \hat{x}(n)$  and  $g(n-i) = \hat{g}(n-i)$ ), we can obtain the convolution of  $x(n)$  and  $g(n)$  by simply convolving  $x_k(n)$  and  $g_k^{(i)}(n)$  and adding the results. No cross convolution between the subband signals is involved. When the computation is done with finite precision, it was also shown in [2] how the energy distribution in the subbands of  $x(n)$  and  $g(n)$  can be exploited to obtain a more accurate (compared to direct convolution) result. Optimal bit allocation and coding gain over the direct convolution were derived for both the cases of uniform and nonuniform decimated systems. In this paper, we further generalize the subband convolution theorem and show that no cross-convolution between the subband signals is involved

in the generalized subband convolution theorem. Then we derive the coding gain for this generalized subband convolver. We will also show that the coding gain for the generalized convolver is always greater than that derived in [2], provided that the filter banks are orthonormal. We will refer to the convolution theorem derived in [2] as *one-level* filter bank (FB) convolution theorem and the generalized theorem in this paper as *two-level* FB convolution theorem. The reason for these names will be made clear in Section II.

In [2], only the quantization in the subbands of  $x(n)$  was considered. In this paper, we will address the case when the subband of  $g(n)$  is quantized. In this case, we quantize the filter coefficients  $g_k^{(i)}(n)$  in the subbands based on the input signal variance, and maximum amplitude of the filter. In the process of quantization, the filter coefficients are treated as *deterministic* parameters instead of random variables as done in [9]. Thus, overflow of subband coefficients is completely avoided. We will derive the optimal bit allocation and the deterministic coding gain formulas. The derivation leads to a novel low sensitivity structure for FIR filters. The new structure is particularly attractive when the filter  $g(n)$  is frequency selective and has a long impulse response, or it has some special time-frequency relation, e.g., the matched filtering of a chirp signal in radar application [10].

In this paper, we also explore the relationship between the convolver and the digital block filtering [11]–[13]. We show that both the one-level and two-level FB convolvers are generalizations of the conventional block filtering. The subband convolvers have both the advantages of coding gain and parallelism. Adaptive filtering in subbands has been introduced with the goals of both reducing the computational complexity and improving the convergence speed of the algorithm. In [14], it was observed that the overall performance of subband adaptive filtering is acceptable though there is some degradation in the convergence performance. In the view of generalized block filtering, the structure used in [14] can be regarded as a simplified version of the two-level FB convolver introduced in this paper. Thus, it is possible to improve the performance of the subband adaptive filter by using the two-level FB convolver.

In the light of block filtering, we generalize the subband convolution technique to implement a linear periodically time varying (LPTV) filter. By using the generalized polyphase representation, we show that interpolated finite impulse response (IFIR) filter [15] is a special case of the subband convolver.

The filter bank techniques have been used in [16] to implement FIR and IIR filters. A different subband convolution theorem which leads to computational saving is derived in [16]. The subband convolution theorem proposed is applied to the digital pulse compression in radar application by Steffen in [10] and the convolution using DFT filter bank is discussed in detail. The subband convolution theorems discussed in this paper and in [2] differ from that derived in [10] and [16] in the sense that the convolution is “perfect” regardless of filter responses of the biorthogonal filter bank. Moreover it works for the nonuniform and maximally decimated cases. Some of the results in this paper have been reported in [17].

## B. Outline of the Paper

Our presentation will go as follows:

- 1) In Section II, we will generalize the subband convolution theorem. This is the two-level FB convolution theorem. A pictorial proof of the theorem is provided in Section II-C to give a clearer insight into what is going on in the convolution theorem.
- 2) In Section III, we consider the quantization of the input signal  $x(n)$ . The optimal bit allocation and coding gain for the two-level FB convolver are presented.
- 3) A low sensitivity structure is derived in Section IV, first using the one-level FB convolver and then the two-level FB convolver. The optimal bit allocation and deterministic coding gain formulas for both the cases will be derived.
- 4) Several numerical examples are included in Section V to demonstrate the usefulness of the low sensitivity structures. From the examples, we will see that the performance of the two-level FB convolver is better than that of the one-level FB convolver. The coding gain of the convolvers is also shown.
- 5) We will discuss the relationship among conventional block filtering, and one-level and two-level FB con-

volvers in Section VI-A. In the presence of quantizers in the subbands of  $g(n)$ , we will show in Section VI that the linear time invariant (LTI) filter is effectively replaced by a LPTV filter in the low sensitivity implementation. We will analyze the effect of this.

- 6) In Section VII, we will give a low sensitivity structure for linear phase filters which can simultaneously exploit the advantage of the coefficient symmetry and coding gain of the FB convolvers.
- 7) In the last section, we will relate the IFIR filter to the subband convolver and consider the problem of implementing IIR filters using FB convolvers.

## C. Notations and Preliminaries

**Notations:** Capital boldfaced letters and lowercase boldfaced letters are used to denote matrices and vectors respectively. The  $(k, i)$ th element of a matrix  $\mathbf{E}$  is denoted by  $[\mathbf{E}]_{ki}$ . The superscript  $*$  denotes complex conjugate and  $\dagger$  denotes conjugate followed by transposition. The  $z$ -transform of  $v(n)$  is represented by  $V(z)$ . The notations  $(V(z))_{\downarrow M}$  and  $(V(z))_{\uparrow M}$  denote the  $M$ -fold decimated and  $M$ -fold expanded versions of the signal  $v(n)$ , respectively. The convolution of  $x(n)$  and  $g(n)$  is denoted by  $x(n) * g(n)$ .

**Quantizers:** The boxes labeled  $Q_i$  in Fig 1(a) are the quantizers. By  $b$  bit quantizer, we mean that the output signal of the quantizer is represented by  $b$  bits plus a sign bit. In this paper, the weight on the most significant bit is fixed for a fixed quantizer.

**The Decimators and Expanders [18]:** The boxes with  $\downarrow n_k$  denote the  $n_k$ -fold decimators and the boxes with  $\uparrow n_k$  denote the  $n_k$ -fold expanders. Their operations can be mathematically described respectively by the following two equations:

$$\begin{aligned} (V(z))_{\downarrow n_k} &= \frac{1}{n_k} \sum_{i=0}^{n_k-1} V(z^{1/n_k} W_{n_k}^i), \\ (V(z))_{\uparrow n_k} &= V(z^{n_k}) \end{aligned} \quad (1)$$

where  $W_{n_k} = e^{-j2\pi/n_k}$ . The subscript  $n_k$  on  $W$  will be omitted whenever it is clear in the discussion.

**Maximal Decimation:** An  $M$ -channel nonuniform multirate system is said to be *maximally decimated* if  $\sum_{i=0}^{M-1} (1/n_k) = 1$ . In the uniform case where all  $n_k$  are equal, this translates to  $n_k = M$  for all  $k$ .

**Conventional Polyphase Representations [3], [19], [18]:** Consider a set of filters  $H_k(z)$ ,  $k = 0, 1, \dots, M-1$ . They can be uniquely written in terms of their  $M$  polyphase components as  $H_k(z) = \sum_{l=0}^{M-1} z^{-l} E_{kl}(z^M)$ . This is known as Type 1 polyphase representation and  $E_{kl}(z)$  is called the  $l$ th polyphase component of  $H_k(z)$ . The  $M \times M$  matrix  $\mathbf{E}(z)$ , with its  $k$ th row  $l$ th column element  $[\mathbf{E}(z)]_{kl} = E_{kl}(z)$ , is called the Type 1 polyphase matrix of the filters  $H_k(z)$ . Similarly,  $H_k(z)$  can be written in terms of their Type 2 polyphase components as  $H_k(z) = \sum_{l=0}^{M-1} z^l R_{lk}(z^M)$ . The Type 2 polyphase matrix  $\mathbf{R}(z)$  of the filters  $H_k(z)$  is defined as  $[\mathbf{R}(z)]_{lk} = R_{lk}(z)$ . These polyphase representations are proved to be valuable in both the theory and design of filter banks.

*Generalized Polyphase Representations* [6], [20]: Generalized polyphase (GPP) was introduced in [6] and used in [20] to enhance the coding gain of subband coding. Instead of expressing a signal  $v(n)$  in terms of the functions  $\{z^{-i}\}$  as in the conventional polyphase representation, we express  $v(n)$  in terms of the functions  $\{U_i(z)\}$  as follows:

$$V(z) = \sum_{i=0}^{M-1} V_i(z^M) U_i(z). \quad (2)$$

This representation is said to be a valid GPP representation if the functions  $\{U_i(z)\}$  (called a "polyphase basis") satisfy the conditions [20]: i) Every rational function  $V(z)$  can be expressed as (2), where  $V_i(z)$  are rational. ii)  $V(z)$  is FIR if and only if  $V_i(z)$  are FIR. By defining  $U(z)$  to be the conventional polyphase matrix of the polyphase basis  $\{U_i(z)\}$ , these conditions were proved to be equivalent to  $\det[U(z)] = cz^k$ , for  $c \neq 0$  and integer  $k$ . We will call  $V_i(z)$  the  $i$ th GPP component of the signal  $v(n)$  with respect to the polyphase basis  $\{U_i(z)\}$ .

*Orthonormality and Biorthogonality* [2], [3], [8], [21]: From Fig. 1(a) (ignore the quantizers in the subbands), the  $z$ -transform of the output of the filter bank is

$$\hat{X}(z) = \sum_{k=0}^{M-1} X_k(z^{n_k}) F_k(z). \quad (3)$$

If  $\hat{x}(n) = x(n)$  for all  $x(n)$ , then the system is called a biorthogonal or perfect reconstruction filter bank. The biorthogonality of the filter bank translates to the following condition on the filters  $H_k(z)$  and  $F_k(z)$ :

$$[H_k(z) F_m(z)]_{|n_{k,m}} = \delta(k - m) \quad (4)$$

where  $n_{k,m} = \gcd(n_k, n_m)$ . From (4), we can see that the perfect reconstruction property is preserved when we interchange the roles of  $H_k(z)$  and  $F_k(z)$ . The set of filters  $\{F_k(z)\}$  is said to be orthonormal if  $(F_k(z) F_m^*(1/z^*))_{|n_{k,m}} = \delta(k - m)$ . In the case of the uniform decimation system, the filter bank is said to be paraunitary if the polyphase matrix  $\mathbf{R}(z)$  of  $\{F_k(z)\}$  satisfies the condition  $\mathbf{R}(z) \mathbf{R}^T(1/z^*) = \mathbf{I}$ , where  $\mathbf{I}$  is the identity matrix.

*Remarks:* For uniform biorthogonal system (all  $n_k = M$ ) with FIR analysis and synthesis filters, (3) is a GPP representation of  $X(z)$  with the polyphase basis  $\{U_i(z)\}$  taken to be  $\{F_i(z)\}$ . The subband signals  $X_k(z)$  can be regarded as the GPP components.

## II. ONE- AND TWO-LEVEL FILTER-BANK CONVOLUTION THEOREM

### A. Review of One-Level FB Convolution Theorem

Consider the two maximally decimated filter banks as shown in Fig. 1 (ignore the quantizers in the discussion of this section). Assume that the system has perfect reconstruction. Then, it was shown in [2] how we can convolve two signals  $x(n)$  and  $g(n)$  by directly convolving the subband signals  $x_k(n)$  and  $g_k^{(i)}(n)$  and adding the results. No cross-coupling between subbands is involved. More precisely, we have the following biorthogonal convolution theorem:

*Theorem 2.1 [2]—One-Level Filter Bank (FB) Convolver:* Consider Fig. 1. Assume that the system has perfect reconstruction. Define the integer  $p_k = L/n_k$ , where  $L$  denotes the least common multiple (lcm) of the decimation ratios  $\{n_k\}$ . Let  $x_k(n)$  and  $g_k^{(i)}(n)$  be the subband signals defined in Fig. 1(a) and (b), respectively. Then, the  $i$ th polyphase component,  $y_i(n)$  of  $x(n) * g(n)$  can be written as

$$y_i(n) = (x(n) * g(n - i))_{\downarrow L} = \sum_{k=0}^{M-1} (x_k(n) * g_k^{(i)}(n))_{\downarrow p_k}. \quad (5)$$

The advantage of the subband convolution is that we can compute the result more accurately when the convolution is implemented with finite precision. It was shown in [2] how we can quantize the subband signals  $x_k(n)$ , and reduce the quantization noise by optimally allocating the bits in the subbands. By exploiting the subband energy distribution, the optimal bit allocation scheme and the coding gain over direct convolution were derived in [2].

*Comments on Complexity:* Notice that the subband convolution theorem holds even when the analysis and the synthesis filters are IIR filters. But if we consider computational cost, the FB convolver is useful only when  $H_k(z)$  and  $F_k(z)$  are FIR filters. Thus in this paper, we will consider subband convolvers with FIR analysis and synthesis filters only. In addition, note that the computation of  $x_k(n)$  involves filtering. Since  $g(n)$  is a fixed filter, the subband signals  $g_k^{(i)}(n)$  can always be precomputed and stored. Thus the complexity of the subband convolution is approximately equal to that of direct convolution plus the cost of implementing an analysis bank, assuming that no fast algorithm for convolution is used. If the complexity of the filter bank is low (compared to the length of the sequences  $x(n)$  and  $g(n)$ ), then the computational cost of  $x_k(n)$  is negligible compared to that of the convolution. In this case the complexity of subband convolution and that of direct convolution are approximately the same.

### B. Two-Level FB Convolution Theorem

*Theorem 2.2—Two-Level FB Convolver:* Let  $H_k(z)$ ,  $F_k(z)$ ,  $n_k$ ,  $p_k$ , and  $L$  be the same as in Theorem 2.1, and let  $\{H'_k(z)\}$  and  $\{F'_k(z)\}$  be respectively the analysis and synthesis filters of a " $L$ -channel" uniform biorthogonal system. Let  $x_k(n)$  and  $g_k^{(i)}(n)$  be respectively the  $k$ th subband signals defined in Fig. 1(a) and Fig. 2. Then the  $i$ th GPP component  $y_i(n)$  of  $x(n) * g(n)$  with respect to the polyphase basis  $\{F'_i(z)\}$ ,  $i = 0, 1, \dots, L-1$  can be written as

$$y_i(n) = \sum_{k=0}^{M-1} (x_k(n) * g_k^{(i)}(n))_{\downarrow p_k}. \quad (6)$$

*Proof:* From the definition of  $X_k(z)$  and  $G_k^{(i)}(z)$  and using the biorthogonality (3) of the filters  $\{H_k(z)\}$  and  $\{F_k(z)\}$ , we get

$$X(z) = \sum_{k=0}^{M-1} X_k(z^{n_k}) F_k(z),$$

Fig. 2. Subband signals of  $g(n)$  in two-level FB convolver.

and

$$G(z)H'_i(z) = \sum_{l=0}^{M-1} G_l^{(i)}(z^{n_l})H_l(z). \quad (7)$$

Multiplying the above two equations and decimating both sides by  $L$ , we have

$$\begin{aligned} [X(z)G(z)H'_i(z)]_{\downarrow L} &= \sum_{k=0}^{M-1} \sum_{l=0}^{M-1} [X_k(z^{n_k/n_{k,l}})G_l^{(i)}(z^{n_l/n_{k,l}})]_{\downarrow p_{k,l}} \\ &\quad \cdot [F_k(z)H_l(z)]_{\downarrow L} \\ &= \sum_{k=0}^{M-1} [X_k(z)G_k^{(i)}(z)]_{\downarrow p_k}, \end{aligned} \quad (8)$$

where  $n_{k,l} = \gcd(n_k, n_l)$  and the integer  $p_{k,l} = L/n_{k,l}$ . The second equality follows from (4) and the fact that  $[V(z)]_{\downarrow L} = [(V(z))_{\downarrow n_{k,l}}]_{\downarrow p_{k,l}}$ . Applying the biorthogonality of the filters  $\{H'_i(z)\}$  and  $\{F'_i(z)\}$  the left hand side of (8) is by definition the  $i$ th GPP component of  $X(z)G(z)$  with respect to the polyphase basis  $\{F'_i(z)\}$ . The proof is complete.  $\square$

Equation (6) gives only the  $i$ th GPP component of  $x(n) * g(n)$ . The convolution output  $y(n)$  can be synthesized from the GPP components as follows:

$$\begin{aligned} Y(z) &= \sum_{i=0}^{L-1} F'_i(z)Y_i(z^L) \\ &= \sum_{i=0}^{M-1} F'_i(z) \sum_{k=0}^{M-1} X_k(z^{n_k})G_k^{(i)}(z^{n_k}). \end{aligned} \quad (9)$$

*Remarks:* Notice that for the uniform case, the corresponding formulas can be obtained by replacing all  $n_k$  with  $M$ , and  $p_k$  with unity. Also notice that even for the nonuniform case, the second-level filter banks with filters  $\{H'_k(z)\}$  and  $\{F'_k(z)\}$  are constrained to be uniform filter banks with decimation ratio  $L = \text{lcm}\{n_k\}$ .

*Comparison of Two-Level FB Convolver with One-Level FB Convolver:* Theorems 2.1 and 2.2 give us respectively the implementations of one-level and two-level FB convolver as Fig. 3(a) and (b). Since  $g(n)$  passes through two levels of filter banks, we call the subband convolver in Fig. 3(b) two-level FB convolver. From these two figures, it is clear that the two-level FB convolver is a generalization of the one-level FB convolver. By taking  $H'_k(z)$  and  $F'_k(z)$  to be  $z^{-i}$  and  $z^i$  respectively, the two-level FB convolver reduce to the one-level FB convolver. As in the one-level FB convolver we see that there is no cross-convolution between subbands in the

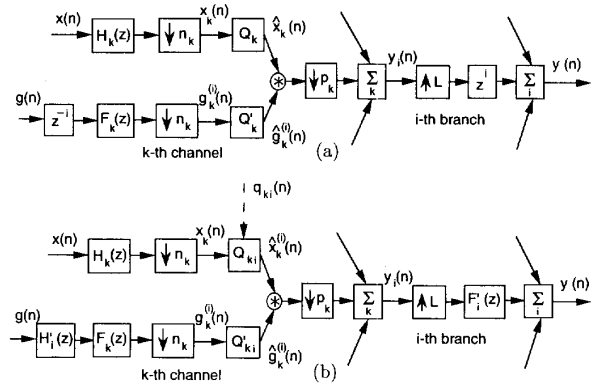

Fig. 3. Implementation of filter bank convolvers: (a) One-level filter bank convolver; (b) two-level filter bank convolver. Asterisk (\*) denotes convolution.

two-level FB convolver. But in order to obtain the convolution output, the outputs of the subband convolutions have to be interpolated by the synthesis filters  $F'_k(z)$  (Fig. 3(b)), instead of just interlacing as in the one-level FB biorthogonal convolution (Fig. 3(a)). The advantage of the two-level FB convolution theorem over the one-level case will be clear when we discuss the low sensitivity FIR filter structure in Section IV. The two-level FB convolver usually computes the convolution much more accurately than the one-level FB convolver, for the same average bit rate. The complexity of the former is that of the latter plus the cost of an additional synthesis bank  $F'_k(z)$  (since  $g_k^{(i)}(n)$  can be precomputed and stored). Thus if the complexity of the filter bank  $\{F'_k(z)\}$  is low, then the complexity of the new subband convolution is comparable to that of direct convolution.

### C. Pictorial Proof of the Subband Convolution Theorem

The above subband convolution theorems can be proved easily by using a sequence of figures. The pictorial proof of Theorem 2.1 leads us naturally to the two-level FB convolution theorem. It also gives a clear insight into what is going on in the subbands, and why perfect convolution is preserved when we pass from the one-level FB convolution theorem to the two-level FB convolution theorem. By using the same technique, the subband convolution theorem has been generalized to the most general case of the multidimensional nonuniform filter banks with rational decimation ratios [22].

Consider Fig. 4(a), where we want to compute  $x(n) * g(n)$ . Clearly, any two identity systems  $I_1$  and  $I_2$  can be inserted before and after the filter  $G(z)$  without changing the convolution output, as shown in Fig. 4(b). If we choose the identity systems to be filter banks with perfect reconstruction, then we can utilize the frequency splitting property of the filter banks and quantize the subband signals according to the energy distribution in each subband. We may also select other identity systems, depending upon the task we want to perform. If we choose  $I_1$  to be the perfect reconstruction system shown in Fig. 1(a), and  $I_2$  to be an  $L$ -channel delay chain, then we can show that the equivalent system shown in Fig. 4(c) is

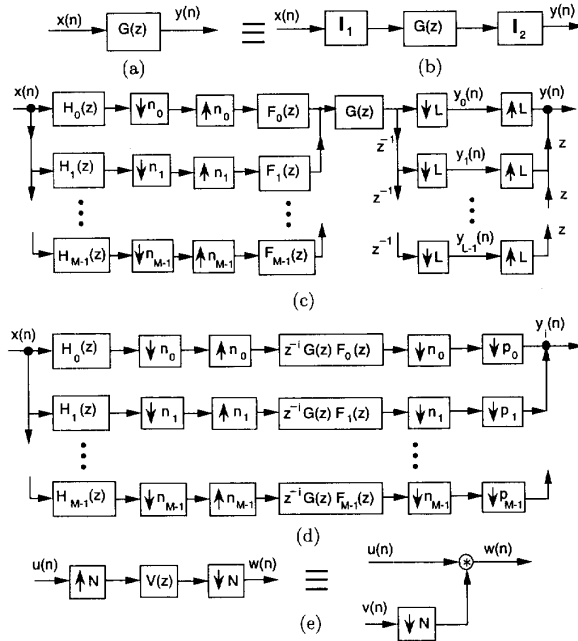

Fig. 4. Pictorial proof of Theorem 2.1: (a) Convolution of  $x(n)$  and  $g(n)$ ; (b) two identity systems inserted; (c) identity systems chosen to be two multirate systems; (d)  $i$ th branch of (c); (e) an identity.

the same as that depicted in Fig. 3(a). By using the fact that  $L = n_k p_k$ , i.e., an  $L$ -fold decimator is equivalent to an  $n_k$ -fold decimator followed by a  $p_k$ -fold decimator, the  $i$ th branch of the system in Fig. 4(c) (i.e., the system from  $x(n)$  to  $y_i(n)$ ) can be redrawn as Fig. 4(d). Applying the identity in Fig. 4(e), it is clear that the system in Fig. 4(d) is equivalent to the  $i$ th branch of the system in Fig. 3(a). This is the one-level FB biorthogonal convolution theorem that we have described in Theorem 2.1.

Similarly, to prove Theorem 2.2, we select  $I_2$  to be an  $L$ -channel biorthogonal filter bank with perfect reconstruction instead of a trivial delay chain. By carrying out exactly the same procedure as above, we can arrive at the result proved in Theorem 2.2.

*Remarks:* In [23], the authors chose  $I_1$  to be a differential pulse coded modulator (DPCM) combined with error spectrum shaping (ESS) and  $I_2$  to be the corresponding differential pulse coded demodulator. In this case,  $I_1$  and  $I_2$  are not identity systems, but the product  $I_1 I_2$  is. Perfect convolution is achieved because all the operations involved are LTI. The authors also showed that high coding gain can be obtained by using such DPCM-ESS convolvers.

### III. CODING GAIN OF TWO-LEVEL FB CONVOLVERS

In this section, we will consider the coding gain for the quantization of the input signal  $x(n)$  only. The filter  $g(n)$  is not quantized. For the case of one-level FB orthonormal convolver, the optimal bit allocation and coding gain were discussed in detail in Sections 3.2 and 3.3, respectively, of [2], for both the uniform and nonuniform cases. For the case

of one-level FB biorthogonal convolver, as the formulas for both the optimal bit allocation and coding gain take exactly the same form as equations (3.16) and (3.17), respectively, of [2]. The only difference is that we cannot prove a result similar to lemmas 3.1 and 3.2 of [2], i.e., the coding gain for the biorthogonal convolver cannot be proved to be always greater than unity. Therefore, we will not elaborate on the one-level FB convolver, but for the two-level FB convolver, as the subband convolution results are interpolated by the synthesis filters  $\{F'_k(z)\}$  as shown in Fig. 3(b), the analysis of the output error due to the quantization in the subband is more complicated. Furthermore, the optimal bit allocation scheme is quite different from that of the one-level FB convolver since the energy of  $H'_i(z)G(z)$  is different in each branch in Fig. 3(b). We will derive the optimal bit allocation and coding gain formulas for the two-level FB convolver in the rest of this section. Since the uniform convolver is strictly a special case of the nonuniform convolver, we will only derive the result for the nonuniform case. The corresponding formulas for the uniform case follow directly by replacing  $L$  and all  $n_k$ 's with  $M$ .

Consider Fig. 3(b). Assume that  $x(n)$ ,  $g(n)$ , and the filter coefficients in all analysis and synthesis filters in the filter bank are real. Then the quantizer operates on real inputs only. Let  $b_{ki}$  be the number of bits per sample of  $x_k(n)$ , allocated to  $Q_{ki}$ , the quantizer in the  $k$ th channel in the  $i$ th branch. Therefore, the average bit rate is

$$b = \frac{1}{L} \sum_{i=0}^{L-1} \sum_{k=0}^{M-1} \frac{b_{ki}}{n_k}. \quad (10)$$

Since  $g_k^{(i)}(n)$  usually have different energy for different  $i$ ,  $b_{ki}$  vary greatly with respect to  $i$  (as we will see later). Therefore, we use double index for the bit rate.

#### A. The Noise Model

The error due to the quantizer  $Q_{ki}$  is defined as

$$q_{ki}(n) \triangleq \hat{x}_k^{(i)}(n) - x_k(n) \quad (11)$$

where  $\hat{x}_k^{(i)}(n)$  is the quantized version of  $x_k(n)$  in the  $i$ th branch. The quantization error can be modeled as an additive noise source. Thus the quantizer  $Q_{ki}$  can be replaced by the broken line as shown in Fig. 3(b).

To analyze the convolution error, we make the following assumptions:

- 1)  $x(n)$  is zero mean wide sense stationary (WSS) with variance  $\sigma_x^2$ . Then  $x_k(n)$  are also WSS, with variance

$$\sigma_{x_k}^2 = \int_0^{2\pi} S_{xx}(e^{j\omega}) |H_k(e^{j\omega})|^2 \frac{d\omega}{2\pi} \quad (12)$$

where  $S_{xx}(e^{j\omega})$  is the power spectrum of  $x(n)$ .

- 2)  $g(n)$  is a deterministic sequence. We define a useful parameter  $\alpha_{ki}^2$  as

$$\alpha_{ki}^2 = M \sum_n |g_k^{(i)}(n)|^2 \quad (13)$$

where  $\alpha_{ki}^2/M$  can be interpreted as the energy of the subband signal  $g_k^{(i)}(n)$ .

- 3)  $q_{ki}(n)$  is zero mean white with variance  $\sigma_{q_{ki}}^2$ , where under certain conditions,  $\sigma_{q_{ki}}^2$  is related to  $\sigma_{x_k}^2$  as

$$\sigma_{q_{ki}}^2 = c\sigma_{x_k}^2 2^{-2b_{ki}}. \quad (14)$$

See [24, ch. 4] or [3, app. C]. Here  $c$  is a constant which depends only on the probability distribution of the subband signals  $x_k(n)$ . We have assumed that  $c$  is independent of  $k$  which is true only if all  $x_k(n)$  have the same probability distribution.

- 4) The cross correlation of  $q_{ki}(n)$  is

$$E\{q_{ki}(n)q_{mi}(l)\} = \sigma_{q_{ki}}^2 \delta(k-m)\delta(n-l), \quad (15a)$$

i.e.,  $q_{ki}(n)$  is uncorrelated to  $q_{mi}(l)$  for  $k \neq m$  and for all  $i, n, l$ . Notice that  $E\{q_{ki}(n)q_{kj}(n)\}$  need not be zero for  $i \neq j$ . We also assume that  $q_{ki}(n)$  is uncorrelated to the subband signals  $x_k(l)$ , that is

$$E\{x_k(l)q_{ki}(n)\} = 0. \quad (15b)$$

#### B. Optimal Bit Allocation and Coding Gain for the Two-Level FB Convolver

To derive the optimal bit allocation and coding gain formulas for the two-level FB convolver, we assume that the second set of synthesis filters  $F'_i(z)$  are orthonormal (or equivalently the uniform filter banks formed by  $\{H'_k(z)\}$  and  $\{F'_k(z)\}$  are paraunitary). Consider Fig. 3(b). The error in the subband convolution output  $y_i(n)$  is

$$q_{yi}(n) = \sum_{k=0}^{M-1} (q_{ki}(n) * g_k^{(i)}(n))_{lp_k}. \quad (16)$$

By using (13)–(15) and the fact that the decimator will not change the variance, the variance of  $q_{yi}(n)$  can be expressed as

$$\begin{aligned} \sigma_{q_{yi}}^2 &= \sum_{k=0}^{M-1} \sigma_{q_{ki}}^2 \sum_l |g_k^{(i)}(l)|^2 \\ &= \frac{c}{M} \sum_{k=0}^{M-1} 2^{-2b_{ki}} \sigma_{x_k}^2 \alpha_{ki}^2, \quad \text{for } 0 \leq i \leq L-1. \end{aligned} \quad (17)$$

Since the synthesis filters  $F'_i(z)$  are orthonormal, the average variance over  $L$  samples,  $\sigma_{q_y}^2$  of the output error is simply the average of  $\sigma_{q_{yi}}^2$ , for  $0 \leq i \leq L-1$ , see [3, sect. C.4.2], [25]. Therefore, we have

$$\sigma_{q_y}^2 = \frac{1}{L} \sum_{i=0}^{L-1} \sigma_{q_{yi}}^2 = \frac{c}{ML} \sum_{i=0}^{L-1} \sum_{k=0}^{M-1} 2^{-2b_{ki}} \sigma_{x_k}^2 \alpha_{ki}^2. \quad (18)$$

To obtain the optimal bit allocation, we minimize the average output noise variance under the constraint (10). We form the Lagrangian

$$\phi = \sigma_{q_y}^2 - \lambda \left( b - \frac{1}{L} \sum_{i=0}^{L-1} \sum_{k=0}^{M-1} \frac{b_{ki}}{n_k} \right). \quad (19)$$

By setting  $\partial\phi/\partial b_{ki} = 0$  for all  $0 \leq i \leq L-1, 0 \leq k \leq M-1$  and  $\partial\phi/\partial\lambda = 0$ , we get

$$\begin{aligned} n_k 2^{-2b_{ki}} \sigma_{x_k}^2 \alpha_{ki}^2 &= D \\ \text{for } 0 \leq i \leq L-1, 0 \leq k \leq M-1 \end{aligned} \quad (20)$$

where  $D$  is a constant independent of  $i$  and  $k$ . Let  $\gamma_k^2$  be the geometric mean of  $\alpha_{ki}^2$  over the index  $i$ , that is

$$\gamma_k^2 = \prod_{i=0}^{L-1} (\alpha_{ki}^2)^{1/L}. \quad (21)$$

By using (10), (20) and (21), we find that

$$D = 2^{-2b} \prod_{k=0}^{M-1} (n_k \sigma_{x_k}^2 \gamma_k^2)^{1/n_k}. \quad (22)$$

Substituting (22) into (20), we find that the optimal number of bits allocated to the quantizer  $Q_{ki}$  at the  $k$ th channel in the  $i$ th branch is

$$\begin{aligned} b_{ki} &= b + 0.5 \log_2(n_k \sigma_{x_k}^2 \alpha_{ki}^2) \\ &\quad - 0.5 \sum_{j=0}^{M-1} \log_2(n_j \sigma_{x_j}^2 \gamma_j^2)^{1/n_j}. \end{aligned} \quad (23)$$

*Periodically Time-Varying Bit Allocation:* From (23), we see that the average bit rate  $b$  must be high enough so that  $b_{ki} \geq 0$  for all  $k$  and  $i$ . Notice that  $b_{ki}$  are integers and the values evaluated by (23) must be rounded off to integers. Intuitively, we would assign more bits to those quantizers in branches where  $g(n) * h'_i(n)$  has higher energy and in channels where  $x_k(n)$  has higher energy. Equation (23) tells exactly how this should be done according to the energy distribution. In the case of the one-level FB convolver, since  $g_k^{(i)}(n)$  is simply obtained by time-shifting  $g(n)$  (see Fig. 3(a)), we would expect that  $\alpha_{ki}^2$  will have very little dependency on  $i$ . In this case,  $b_{ki}$  are the same for all  $i$  and (23) reduces to equation (3.32) of [2]. However, in the case of the two-level FB convolver,  $\alpha_{ki}^2$  may differ greatly for different  $i$ , especially when the filter  $g(n)$  is a frequency selective filter (which is usually the case). Then,  $b_{ki}$  may vary greatly with respect to  $i$ . In this case, not all branches are equally important as in the case of the one-level FB convolver, and the coding gain may increase significantly by using this “periodically time-varying” bit allocation scheme.

By using (20) and (22) and the fact that the filter bank is maximally decimated, i.e.,  $\sum_{k=0}^{M-1} (1/n_k) = 1$ , we find that the average output noise variance under optimal bit allocation is

$$\sigma_{q_y, \text{opt}}^2 = \frac{cD}{M} = \frac{c}{M} 2^{-2b} \prod_{k=0}^{M-1} (n_k \sigma_{x_k}^2 \gamma_k^2)^{1/n_k}. \quad (24)$$

If  $x(n)$  is quantized to  $b$  bits, then in the direct convolution the output noise variance due the quantization is found to be

$$\sigma_{\text{direct}}^2 = c2^{-2b}\sigma_x^2 \sum_l |g(l)|^2. \quad (25)$$

Under optimal bit allocation, the coding gain of the two-level FB convolver over the direct form is

$$G_{x,\text{two}} = \frac{\text{output variance}|_{\text{direct conv}}}{\text{output variance}|_{\text{subband conv}}} = \frac{\sigma_x^2}{\prod_{i=0}^{M-1} (\sigma_{x_i}^2)^{1/n_i}} \times \frac{\sum_n |g(n)|^2}{\frac{1}{M} \prod_{i=0}^{M-1} (n_i \gamma_i^2)^{1/n_i}}. \quad (26)$$

The “ $x$ , two” in the subscript in (26) indicates that the coding gain is obtained by using the two-level FB convolver and quantizing the signal  $x(n)$ . This subscript is used to distinguish (26) from the deterministic coding gain which is obtained by quantizing  $g(n)$  in the next section. From the right hand side of (26), we see that the variation of subband energy of both  $x(n)$  and  $g(n)$  contributes to the coding gain. The first term is the gain contributed by  $x(n)$  and the second term is the gain contributed by  $g(n)$ .

*Summary of Crucial Assumptions:* In the derivation of (26), we have assumed that the constant  $c$  in (25) is the same as that in (14) which is true only if  $x(n)$  and all  $x_k(n)$  have the same probability distribution. In addition, in the above derivation, we have made use of the orthonormality of the filters  $\{F_k(z)\}$  and the uncorrelated assumptions of  $q_{ki}(n)$ . Notice that only the *biorthogonality* of the filters  $\{F_k(z)\}$  and  $\{H_k(z)\}$  is required for (26) to be valid, orthonormality of those filters being not necessary. However, without the orthonormality of those filters, we *cannot* guarantee that the optimal coding gain in (26) is always greater than unity. If the filters  $\{F_k(z)\}$  are orthonormal, then we can prove that the coding gain for the two-level FB convolver is always greater than unity, regardless of the *quality* of the filters  $\{H_k(z)\}$ ,  $\{F_k(z)\}$ ,  $\{H'_k(z)\}$  and  $\{F'_k(z)\}$ . Moreover, we can prove that this coding gain is never smaller than that of the one-level FB convolver derived in Section 3.3 of [2], provided that  $x(n)$ ,  $g(n)$ ,  $\{H_k(z)\}$  in both cases are the same. More precisely, we have the following lemma.

**Lemma 3.1:** The coding gain  $G_{x,\text{two}}$  of the two-level orthonormal FB convolver (i.e., FB in both levels are orthonormal) is never smaller than that of the one-level orthonormal FB convolver, regardless of the choice of paraunitary filters  $\{H'_k(z)\}$ , provided that  $x(n)$ ,  $g(n)$ ,  $\{H_k(z)\}$  in both cases are the same. Moreover, they are equal if and only if the sequence  $g_k^{(i)}(n)$  has the same energy for all  $0 \leq i \leq L-1$ .

In [2], it was shown that under optimal bit allocation, the coding gain of the one-level FB convolver is

$$G_{x,\text{one}} = \frac{\sigma_x^2}{\prod_{i=0}^{M-1} (\sigma_{x_i}^2)^{1/n_i}} \times \frac{\sum_n |g(n)|^2}{\frac{1}{M} \prod_{i=0}^{M-1} (n_i \alpha_i^2)^{1/n_i}}, \quad (27)$$

Fig. 5. Relationship between the subband signals of the one-level and two-level FB convolvers.

where  $\alpha_k^2$  is defined as

$$\alpha_k^2 = \frac{M}{L} \sum_{i=0}^{L-1} \sum_n |g_{k,\text{one}}^{(i)}(n)|^2 \quad (28)$$

where the “one” in the subscript is used to denote that  $g_{k,\text{one}}^{(i)}(n)$  are the subband filters of the one-level FB convolver (see Fig. 5). Comparing (27) with (26), we find that the coding gain formulas for both the one-level and two-level FB convolvers are very similar, except that  $\alpha_k^2$  is replaced by  $\gamma_k^2$ . Therefore in the following proof of Lemma 3.1, we need to establish the relation between  $\alpha_k^2$  and  $\gamma_k^2$ .

*Proof:* By defining

$$\mathbf{h}'(z) = [H'_0(z)H'_1(z) \cdots H'_{L-1}(z)]^T$$

and

$$\mathbf{e}(z) = [1 z^{-1} \cdots z^{-(L-1)}]^T$$

we have  $\mathbf{h}'(z) = \mathbf{E}'(z^L) \mathbf{e}(z)$ , where  $\mathbf{E}'(z)$  is the  $L \times L$  polyphase matrix of  $\mathbf{h}'(z)$ . From the definition of  $g_k^{(i)}(n)$  and  $g_{k,\text{one}}^{(i)}(n)$ , it is clear that  $g_k^{(i)}(n)$  can be obtained by passing  $g_{k,\text{one}}^{(i)}(n)$  through  $\mathbf{E}'(z^{p_k})$  as shown in Fig. 5. Since  $\mathbf{E}'(z)$  is paraunitary, we have [25]

$$\sum_{i=0}^{L-1} \sum_n |g_k^{(i)}(n)|^2 = \sum_{i=0}^{L-1} \sum_n |g_{k,\text{one}}^{(i)}(n)|^2. \quad (29)$$

By using (13), (28) and (29), we find the following important equality

$$\alpha_k^2 = \frac{1}{L} \sum_{i=0}^{L-1} \alpha_{ki}^2 = \text{arithmetic mean of } \alpha_{ki}^2. \quad (30)$$

By taking the ratio of  $G_{x,\text{two}}$  to  $G_{x,\text{one}}$ , we find that the ratio of the coding gain of the two-level FB convolver to that of the one-level FB convolver is

$$R_x = \prod_{i=0}^{M-1} \left( \frac{\alpha_k^2}{\gamma_k^2} \right)^{1/n_k}. \quad (31)$$

Using (21) and (30) and applying the AM-GM inequality, each term in the product in (31) is greater or equal to unity with equality if and only if  $\alpha_{ki}^2 = \alpha_k^2$  for all  $i$ . Therefore, we conclude that  $R_x \geq 1$ , with equality if and only if  $\alpha_{ki}^2 = \alpha_k^2 = \gamma_k^2$  for all  $i$ , or equivalently, the sequences  $g_k^{(i)}(n)$  have the same energy for all  $0 \leq i \leq L-1$ .  $\square$

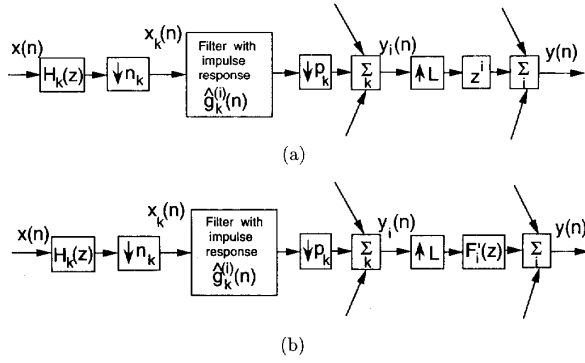

Fig. 6. Low-sensitivity structures for FIR filters: (a) With one-level filter bank convolver; (b) with two-level filter bank convolver.

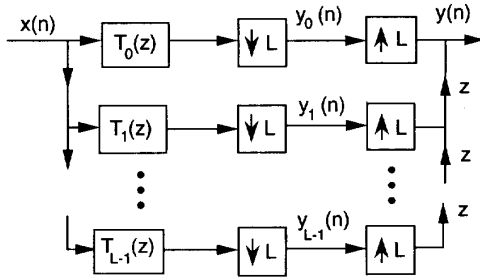

Fig. 7. Representation of an LPTV system.

**Corollary 3.1:**  $G_{x,two} \geq 1$  for the two-level orthonormal FB convolver, regardless of the choice of the orthonormal sets of filters  $\{H_k(z)\}$  and  $\{H'_k(z)\}$ . Equality holds if and only if both  $\sigma_{x_k}^2$  and  $n_k \alpha_{k,i}^2$  are independent of  $k$  and  $i$ .  $\diamond$

*Proof:* This follows directly from the above lemma and lemma 3.2 of [2].  $\square$

#### IV. LOW-SENSITIVITY STRUCTURE FOR FIR FILTERS AND DETERMINISTIC CODING GAIN

Ignore the quantizers in the subbands of  $x(n)$  for the discussion of this section. Very similar to the idea of quantizing  $x(n)$ , we can quantize the filter coefficients  $g_k(n)$  in the subbands based on the input signal variance and maximum amplitude of the subband filter coefficients. However, the coefficients have to be treated as deterministic parameters so that overflow is avoided completely. In this implementation, the convolution error due to the coefficient quantization is much smaller than that in the direct form implementation. Let  $\hat{g}_k^{(i)}(n)$  be the quantized version of  $g_k^{(i)}(n)$ . Then, we can redraw Fig. 3(a) and (b) as Fig. 6(a) and (b), respectively. The implementations in Fig. 6(a) and (b) can be regarded as low sensitivity implementations of the filter  $g(n)$ . In this section, we will discuss in detail first the optimal bit allocation and the coding gain over direct form for the one-level FB convolver and then for the two-level FB convolver. Again, we will only derive the formulas for the nonuniform case. The corresponding formulas for the uniform case can be obtained by simply replacing  $n_k$  and  $L$  with  $M$ . For a preview of the advantage of the implementation, compare Figs. 8 and 9.

Fig. 8. Magnitude response of  $g(n)$  with direct quantization to 4 b and without quantization.

Fig. 9. Example 1—Magnitude response of  $g(n)$  with subband quantization to 4 b by using one-level FB convolver.

When the same average number of bits is used to quantize the filter coefficients for direct convolution (Fig. 8) and subband convolution (Fig. 9), the improvement shown in these figures is significant. In the rest of this section, we will translate this improvement into a mathematical formula.

##### A. Low-Sensitivity FIR Filter Structures Using the One-Level FB Convolver

With the quantizers inserted in the subbands of  $g(n)$  as in Fig. 3(a), let  $b_k$  be the number of bits per sample of  $g_k(n)$ , allocated to the quantizers  $Q'_k$ . Then, the average bit rate  $b$  is defined as

$$b = \sum_{k=0}^{M-1} \frac{b_k}{n_k}. \quad (32)$$

**1. The Noise Model:** Define the deterministic quantization error to be

$$q_k^{(i)}(n) \triangleq \hat{g}_k^{(i)}(n) - g_k^{(i)}(n) \quad (33)$$

where  $\hat{g}_k^{(i)}(n)$  is the quantized version of  $g_k^{(i)}(n)$ . To avoid overflow in the filter coefficients, we assume that the weighting of the most significant bit assigned to the quantizer  $Q'_k$  is greater than  $g_{k,\max}$ , where

$$g_{k,\max} = \max_{i,n} |g_k^{(i)}(n)|. \quad (34)$$

Under this condition, the stepsize in the  $k$ th quantizer would be  $\Delta_k = c_1 g_{k,\max} 2^{-b_k}$  and the mean square value of the

quantization error  $q_k^{(i)}(n)$  is

$$\sigma_{q_k^{(i)}}^2 = 1/L_{g_k} \sum_{n=0}^{L_{g_k}-1} |q_k^{(i)}(n)|^2 = c_2 g_{k,\max}^2 2^{-2b_k} \quad (35)$$

where  $c_1$  and  $c_2$  are constants independent of  $k$  and  $i$ ,  $L_{g_k}$  is the length of the subband filter  $g_k^{(i)}(n)$ . In practice,  $c_1$  and  $c_2$  will depend on  $g_k^{(i)}(n)$ , but the bit allocation and coding gain is insensitive to the variation of these constants. To carry on the analysis, we assume that they are constant. We further assume that

- 1)  $x(n)$  is WSS as assumed in the previous section
- 2) the deterministic cross correlation of the quantization error  $q_k^{(i)}(n)$  approximately satisfies

$$\frac{1}{L_{g_k}} \sum_{p=0}^{L_{g_k}-1} q_k^{(i)}(p) q_j^{(i)}(p+m) \approx \sigma_{q_k^{(i)}}^2 \delta(k-j) \delta(m). \quad (36)$$

This is, of course, never exact because  $q_k^{(i)}(n)$  is FIR.

- 3) The length  $L_g$  of  $g(n)$  is much greater than that of the analysis filters. Therefore,  $L_{g_k} \approx L_g/n_k$ . This is usually the case if the filter bank is of low complexity.

**2. The Optimal Bit Allocation and the Deterministic Coding Gain:** Consider Fig. 6(a). The error of the subband convolution output  $y_i(n)$ , due to quantization of  $g_k^{(i)}(n)$ , can be expressed as

$$q_{y_i}(n) = \sum_{k=0}^{M-1} (x_k(n) * q_k^{(i)}(n)) \downarrow_{p_k}. \quad (37)$$

By using the assumptions in the noise model and carrying out the exact same procedure in Section III, we find that the optimal number of bits used to quantize the subband filter  $g_k^{(i)}(n)$  is

$$b_k = b + 0.5 \log_2 \sigma_{x_k}^2 g_{k,\max}^2 - 0.5 \sum_{i=0}^{M-1} \log_2 (\sigma_{x_i}^2 g_{i,\max}^2)^{1/n_i}. \quad (38)$$

Under this optimal bit allocation, the average output variance is

$$\sigma_{q_{y,\text{opt}}}^2 = c L_g 2^{-2b} \prod_{k=0}^{M-1} (\sigma_{x_k}^2 g_{k,\max}^2)^{1/n_k}. \quad (39)$$

In contrast, suppose we have convolved directly (i.e., without any filter bank). If  $g(n)$  is quantized to  $b$  bits and without coefficient overflow, then the output error variance is

$$\sigma_{\text{direct}}^2 = c L_g 2^{-2b} g_{\max}^2 \sigma_x^2 \quad (40)$$

where  $g_{\max} = \max_n |g(n)|$ .

Therefore, from (39) and (40), we find that the deterministic coding gain of the one-level FB convolver over the direct form

is

$$G_{g,\text{one}} = \frac{\sigma_x^2}{\prod_{k=0}^{M-1} (\sigma_{x_k}^2)^{1/n_k}} \times \frac{g_{\max}^2}{\prod_{k=0}^{M-1} (g_{k,\max}^2)^{1/n_k}}. \quad (41)$$

**A Lower Bound for the Coding Gain:** In the above derivation, orthonormality property of the filter bank is not required, biorthogonality is sufficient. As there is no strong relationship between  $g_{k,\max}$  and  $g_{\max}$ , even for the case of orthonormal convolver, the deterministic coding gain cannot be proved to be always greater than unity. The likelihood that the deterministic coding gain is less than unity is very low. In fact, in all the examples we encountered in numerical experiments, the coding gain is quite large. However, if the analysis and synthesis filters have unit energy (this condition indeed implies that the biorthogonal filter bank is orthonormal [26]), we can obtain a (very pessimistic) lower bound for the coding gain. From Appendix A, we have the following very loose relationship between  $g_{k,\max}$  and  $g_{\max}$ :

$$g_{k,\max} \leq \sqrt{L_{H_k}} g_{\max} \quad (42)$$

where  $L_{H_k}$  is the length of the filter  $H_k(z)$ . Substituting (42) into (41), we find that the coding gain is lower bounded as

$$G_{g,\text{one}} \geq \frac{\sigma_x^2}{\prod_{k=0}^{M-1} (L_{H_k} \sigma_{x_k}^2)^{1/n_k}}. \quad (43)$$

**Remarks:** We can also define  $g_{ki,\max} = \max_n |g_k^{(i)}(n)|$  in the noise model. Based on these parameters, we can minimize the output error variance by using "periodically time-varying" bit allocation scheme (that is, use  $b_{ki}$  instead of  $b_k$ ). Although this is more general than what have been done above, the improvement is negligible for the one-level FB convolver. The reason is that in this convolver,  $g_k^{(i)}(n)$  is obtained by time-shifting the input  $g(n)$ , and  $g_{k,\max}^{(i)}$  would not vary very much with respect to  $i$ . In fact, in all the numerical experiments we carried out, we find that all  $b_{ki}$  are the same for all  $i$ , even if we allow periodically time-varying bit allocation. However, in the case of the two-level FB convolver, this is not true. The coding gain usually increases by a large amount if a periodically time-varying bit allocation scheme is employed.

## B. Low Sensitivity FIR Filter Structures Using the Two-Level FB Convolver

We can implement FIR filters using the two-level FB convolver instead of the one-level FB convolver. This will give a lower sensitivity (i.e., provide a much higher deterministic coding gain). Or equivalently, we can afford to quantize the subband filters  $g_k^{(i)}(n)$  to a much lower bit rate for a fixed accuracy. The optimal bit allocation and deterministic coding gain will be derived in the following. Again for a preview of the advantage of the two-level FB convolver over the one-level FB convolver, compare Figs. 9 and 11. The equivalent filter responses for both the cases are comparable even though the

Fig. 10. Example 1—Group delay of  $g(n)$  with subband quantization to 4 b by using the one-level FB convolver.

Fig. 11. Example 2—Magnitude response of  $g(n)$  with subband quantization to 2 b by using two-level FB convolver.

average number of bits used in the two-level FB convolver (2 b) is only half of that used in one-level FB convolver (4 b).

Consider Fig. 6(b). Let  $b_{ki}$  be the number of bits used to quantize the subband filter  $g_k^{(i)}(n)$ . Then the average bit rate  $b$  is defined as in (10). The noise model assumed here is the same as that in Section IV-A except that (35) is replaced with

$$\sigma_{q_k^{(i)}}^2 = 1/L_{g_k} \sum_{n=0}^{L_{g_k}-1} |q_k^{(i)}(n)|^2 = c_2 g_{ki,\max}^2 2^{-2b_{ki}} \quad (44)$$

where

$$g_{ki,\max} \triangleq \max_n |g_k^{(i)}(n)|. \quad (45)$$

*1. The Optimal Bit Allocation and the Deterministic Coding Gain:* The error at the location  $y_i(n)$  in Fig. 6(b) can be expressed as (37). To carry on the analysis, we will assume that the filter bank  $\{F'_i(z)\}$  is paraunitary. By using the same technique as in the previous section, we find that the optimal bit used to quantize  $g_k^{(i)}(n)$  is

$$b_{ki} = b + 0.5 \log_2 \sigma_{x_k}^2 g_{ki,\max}^2 - 0.5 \sum_{j=0}^{M-1} \log_2 (\sigma_{x_j}^2 \beta_j^2)^{1/n_j} \quad (46)$$

where

$$\beta_k^2 = \prod_{i=0}^{L-1} (g_{ki,\max}^2)^{1/L} = \text{geometric mean of } g_{ki,\max}^2. \quad (47)$$

The average output noise variance under optimal bit allocation is

$$\sigma_{q_y,\text{opt}}^2 = c L_g 2^{-2b} \prod_{k=0}^{M-1} (\sigma_{x_k}^2 \beta_k^2). \quad (48)$$

From (40) and (48), we find that the deterministic coding gain of the two-level FB convolver over the direct form is

$$G_{g,\text{two}} = \frac{\sigma_x^2}{\prod_{k=0}^{M-1} (\sigma_{x_k}^2)^{1/n_k}} \times \frac{g_{\max}^2}{\prod_{k=0}^{M-1} (\beta_k^2)^{1/n_k}}. \quad (49)$$

*A Lower Bound for the Coding Gain:* Again, we cannot show that the coding gain is always greater than unity, but by exploiting the result from Appendix A (with  $h_k(n)$  replaced with  $h_k(n) * h'_i(n)$ ), we can obtain a (very pessimistic) lower bound similar to (43) for the coding gain. The lower bound is

$$G_{g,\text{two}} \geq \frac{\sigma_x^2}{\prod_{k=0}^{M-1} ((L_{H_k} + L_{H'_i} - 1) \sigma_{x_k}^2)^{1/n_k}} \quad (50)$$

where  $L_{H'_i}$  is the length of the analysis filter  $H'_i(z)$ , assumed to be the same for all  $i$ . By taking the ratio of (49) to (41), we find that the ratio of the deterministic coding gain of the two-level FB convolver to that of the one-level FB convolver is

$$R_g = \prod_{k=0}^{M-1} \left( \frac{g_{k,\max}^2}{\beta_k^2} \right)^{1/n_k}. \quad (51)$$

*Comparisons of Results:* Comparing the coding gain formulas in all the cases ( $G_{x,\text{one}}$ ,  $G_{x,\text{two}}$ ,  $G_{g,\text{one}}$  and  $G_{g,\text{two}}$ ), we find that all of them have the following form

$$G = \frac{\sigma_x^2}{\prod_{i=0}^{M-1} (\sigma_{x_i}^2)^{1/n_i}} \times \frac{A^2}{\prod_{i=0}^{M-1} (A_i^2)^{1/n_i}}. \quad (52)$$

All of them have a common first factor which is always greater than unity when the filter bank is orthonormal. They differ only in the second factor. All of them can be obtained by substituting  $A^2$  and  $A_i^2$  with the corresponding parameters. The only difference is that unlike in the case of the statistical coding gain in Section III, for the deterministic coding gain we cannot prove a result similar to (30), that is, we cannot prove that  $g_{k,\max}^2$  is the arithmetic mean of  $g_{ki,\max}^2$ , even if the filter  $H'_i(z)$  is paraunitary. Therefore, the ratio of the deterministic coding gain  $R_g$  in (51) cannot be proved to be always greater than one. Nevertheless, in practice, we will find that  $\beta_k^2$  is usually much smaller than  $g_{k,\max}^2$  for a frequency selective filter  $g(n)$ . The reason is that under usual situations, the arithmetic mean of  $g_{ki,\max}^2$  would not differ much from  $g_{k,\max}^2$ . However,  $g_{ki,\max}^2$  may vary considerably with respect

TABLE I  
SUMMARY OF EXAMPLES 1-4

	$b$	$\delta_s$ (dB)	$\delta_p$
No Quantization	—	-60	0.010
Direct Quantization	4	-17	0.049
4ch PU Bank: 1-level	4	-42	0.013
4ch PU Bank: 2-level	2	-44	0.015
4 × 4 DCT: 1-level	4	-32	0.022
8 × 8 DCT: 1-level	4	-38	0.012
4 × 4 DCT: 2-level	2	-27	0.035
8 × 8 DCT: 2-level	2	-33	0.017

to  $i$  if  $g(n)$  is frequency selective. Thus, we may expect that the coding in (49) would be much larger than that in (41) as we will see in the numerical examples in the following section.

*Coding Gain when Both Input Signal  $x(n)$  and Filter  $g(n)$  are Quantized:* When quantizers are inserted in both the subbands of  $x(n)$  and  $g(n)$ , the coding gain is not the product of  $G_x$  and  $G_g$ . To obtain the coding gain, we apply the optimal bit allocation formulas in (23) and (46), respectively, to the quantization of  $x_k(n)$  and  $g_k^{(i)}(n)$ , and ignore the second-order effect. The coding gain is

$$G = \frac{\{\sigma_{q_y, \text{opt}}^2\}_x + \{\sigma_{q_y, \text{opt}}^2\}_g}{\{\sigma_{\text{direct}}^2\}_x + \{\sigma_{\text{direct}}^2\}_g} \quad (53)$$

where the subscript “ $x$ ” is used to denote the case when only  $x(n)$  is quantized, and “ $g$ ” is used to denote the case when only  $g(n)$  is quantized. We see that the largest error term in (53) will dominate the coding gain.

## V. NUMERICAL EXAMPLES

In this section, only  $g_k(n)$  are quantized but not  $x_k(n)$ . In the presence of quantizers in the subbands of  $g(n)$ , the LTI system with impulse response  $g(n)$  is effectively replaced with a periodically time varying system (LPTV) (see section 10.1 of [3] for an introduction to LPTV system) with period  $L$  (see the next section for the discussion). To describe the system, we have to characterize all  $L$  transfer functions  $T_k(z)$  as shown in Fig. 7. In all the following examples, we therefore show all transfer functions.

In the first four examples,  $g(n)$  is an equiripple low-pass filter with  $L_g = 132$ . The stopband attenuation  $\delta_s = -60$  dB and the passband ripple size  $\delta_p = 0.010$ . The frequency responses of  $g(n)$  with direct quantization to 4 bits and without quantization are shown in Fig. 8, the stopband attenuation reduces to -17 dB and the passband ripple size increases to 0.049 after quantization. In these four examples, we will show the equivalent filters if we implement  $g(n)$  by using the low-sensitivity structures (Fig. 6(a) and (b)). For comparison of the results in the first four examples, we summary the main features in Table I. In the last two examples, we will show the deterministic coding gain and verify the theoretical values with the experimental values.

8 × 8 DCT	9	9	6	3	3	1	1	0

*Example 1—Four-Channel Paraunitary (PU) Filter Bank (One-Level FB Convolver):*  $L = M = 4$ , and  $b = 4$  b. The four-channel filter bank in Fig. 6(a) is taken to be a tree-structured PU filter bank obtained by using two-channel PU filter bank in a symmetric tree. The two-channel PU system uses Filter 8A in [27]. If we implement the analysis bank  $\{H_k(z)\}$  in lattice form, we need only eight multiplications per input sample. The corresponding optimal bit allocation is  $b_0 = 10$ ,  $b_1 = 5$ ,  $b_2 = 1$ ,  $b_3 = 0$  bits. As shown in Fig. 9, the stopband attenuations of all the four filters  $T_i(z)$  are more than 42 dB, i.e., more than 25 dB better than that of the direct quantization. The passband ripple  $\delta_p = 0.013$ . The effect of quantization on the ripple size is negligible. To visualize the effect of the quantization on the phase response, we show the phase responses of  $z^i T_i(z)$  in Fig. 10. From the plots, we see that the phase distortion in the passband is negligible.

*Example 2—Four-Channel PU Filter Bank (Two-Level FB Convolver):*  $L = M = 4$ , and  $b = 2$  b. Both the filter banks formed by  $\{H_k(z)\}$  and  $\{H'_i(z)\}$  are taken to be the filter bank used in Example 1. The corresponding bit allocation is shown in Table II. As we would expect,  $b_{ki}$  are large for  $i = 0$  because most of the energy of  $G(z)$  is in the first branch. As shown in Fig. 11, the stop-band attenuations (44 dB) are comparable to that obtained in Example 1 but the average bit rate  $b$  is reduced to half. The passband ripple  $\delta_p = 0.015$ .

*Example 3—Four- and Eight-Channel DCT Coders (One-Level FB Convolver):*  $b = 4$  b, and we use the DCT filter bank, which is shown in Fig. 6 of [2]. In a transform coder filter bank, the polyphase matrix  $\mathbf{E}(z)$  of the analysis filters is a constant matrix  $\mathbf{T}$ . In this example, two cases of  $\mathbf{T}$  are considered: i) 4 × 4 DCT matrix and ii) 8 × 8 DCT matrix, as defined in equation (12.157) of [24]. DCT has the advantage that the analysis filters have linear phase, and there exists a fast algorithm for the computation of DCT. The corresponding bit allocations are shown in Table III. For each case, we show only one transfer function  $T_0(z)$  in Fig. 12 for simplicity. We see that for  $M = 4$ , the stop-band attenuation is 32 dB, and  $\delta_p = 0.022$ . For  $M = 8$ , the stopband attenuation is 38 dB and  $\delta_p = 0.012$ .

*Example 4—Four- and Eight-Channel DCT Coders (Two-Level FB Convolver):*  $b = 2$  b. The filter bank used

Fig. 12. Example 3—Magnitude response of  $g(n)$  with subband quantization to 4 b by using one-level FB convolver.

Fig. 13. Example 4—Magnitude response of  $g(n)$  with subband quantization to 2 b by using two-level FB convolver.

TABLE IV  
EXAMPLE 4(i)—THE NUMBER OF BITS  $b_{ki}$  ALLOCATED TO  $Q'_{ki}$

$k =$	0	1	2	3
$i = 0$	7	6	3	0
$i = 1$	5	5	2	0
$i = 2$	2	2	0	0
$i = 3$	0	0	0	0

TABLE V  
EXAMPLE 4(ii)—THE NUMBER OF BITS  $b_{ki}$  ALLOCATED TO  $Q'_{ki}$

$k =$	0	1	2	3	4	5	6	7
$i = 0$	9	7	8	5	5	2	2	0
$i = 1$	7	9	7	4	4	2	1	0
$i = 2$	7	6	6	3	3	1	0	0
$i = 3$	3	4	3	1	0	0	0	0
$i = 4$	4	3	3	0	0	0	0	0
$i = 5$	2	1	1	0	0	0	0	0
$i = 6$	2	1	2	0	0	0	0	0
$i = 7$	0	0	0	0	0	0	0	0

here is the same as Example 3. In addition,  $\{H'_k(z)\}$  is identical to  $\{H_k(z)\}$ . The optimal bit allocation for  $4 \times 4$  DCT is shown in Table IV. The corresponding optimal bit allocation for  $8 \times 8$  DCT is shown in Table V. For simplicity, we show only  $T_0(z)$  in Fig. 13. The stop-band attenuations for  $M = 4$  and  $M = 8$  are 27 and 30 dB, respectively. The passband ripple size increases to 0.035 and 0.026, respectively, for  $M = 4$  and  $M = 8$ .

**Example 5—Coding Gain (One-Level FB Convolver):**  $M = 4$  and  $b = 8$  b. The filter bank used here is the same as that used in Example 1. The input signal  $x(n)$  is taken to be an AR(5) process with autocorrelation coefficients  $R(k)$  obtained from Table II of [24] (low-pass speech source). The first two rows of Table VI show, respectively, the coding gain obtained from (41) ( $G_{g,one}$ ) and that obtained from experiment ( $G_{g,expt,one}$ ) for five different filters  $g(n)$  (Filter 1 is the  $g(n)$  used in the previous four examples). In most cases, the theoretical value obtained from (41) is very close to the experimental result, in spite of the many statistical assumptions used.

TABLE VI  
EXAMPLES 5 AND 6—COMPARISON OF CODING GAIN

Filter No.	1	2	3	4	5
$G_{f,one}$ (dB)	33.2	19.3	17.6	26.4	36.6
$G_{f,expt,one}$ (dB)	33.5	19.8	15.5	20.9	34.5
$G_{f,two}$ (dB)	47.6	28.0	26.5	38.7	54.3
$G_{f,expt,two}$ (dB)	49.5	28.5	25.8	36.7	51.9
$R_g$ (dB)	14.4	8.7	8.9	12.3	17.7
$R_{g,expt}$ (dB)	16.0	8.7	10.3	15.8	17.4

**Example 6—Coding Gain (Two-Level FB Convolver):** The filter bank formed by  $\{H'_i(z)\}$  is identical to that formed by  $\{H_k(z)\}$  and other conditions are the same as those in Example 5. The coding gain obtained from (49) ( $G_{g,two}$ ) and that obtained from experiment ( $G_{g,expt,two}$ ) for the same set of five different filters  $g(n)$  are shown in the third and fourth rows of Table VI, respectively. Again, we see that the theoretical values are very close to the experiment results. The performance of the two-level FB convolvers is much better (8.7–17.4 dB or equivalently 1.5–3 b approximately) than that of one-level FB convolvers for all the five cases. The ratios of the coding gain for the two-level FB convolver to that of the one-level FB convolver,  $R_g$  (theoretical) and  $R_{g,expt}$  (experimental) are shown in the last two rows of Table VI.

From the first four examples, we notice that the performance of the DCT coder is not as good as that of the PU filter bank transformer in Example 1 and 2. The reason is that the analysis filters of the DCT coder have a smaller stopband attenuation. The leakage from the adjacent band is quite large. In the last two examples, we see that the deterministic coding gain for the two-level FB convolver is much larger than that of the one-level FB convolver although we cannot prove theoretically that this is always true. By using the two-level FB convolvers, we get a much higher accuracy at the expense of the cost of one filter bank.

## VI. RELATION TO BLOCK FILTER AND ALIASING EFFECT

### A. Convolvers in the View of Block Filter

It is well-known (see [11]–[13], [6], and chapter 10 of [3]) that block filtering is a technique to implement a scalar filter

$G(z)$  in such a way as to increase the parallelism. In this section, we will explore the relationship between the filter bank convolver and the conventional block filtering technique. It was shown in [28] that the nonuniform system of Fig. 1 can be expanded as an  $L$ -channel uniform system. The  $M$  pairs of filters  $\{H_k(z), F_k(z)\}$  in the nonuniform system are replaced by the  $L$  pairs of filters, say  $\{H_k(z), F_k(z)\}$ , in the uniform system. We will discuss the uniform case only, as the nonuniform problem can be translated to uniform case.

**1. Conventional Block Filtering:** Given any scalar filter  $G(z)$ , we can implement it by using block filtering technique as shown in Fig. 14(a). The matrix  $\mathbf{G}(z)$  in Fig. 14(a) is a pseudocirculant matrix and it can be written as:

$$\mathbf{G}(z) = \begin{pmatrix} G_0(z) & G_1(z) & \cdots & G_{M-1}(z) \\ z^{-1}G_{M-1}(z) & G_0(z) & \cdots & G_{M-2}(z) \\ \vdots & \vdots & \ddots & \vdots \\ z^{-1}G_1(z) & z^{-1}G_2(z) & \cdots & G_0(z) \end{pmatrix} \quad (54)$$

where  $G_i(z)$  is the  $i$ th polyphase component of the scalar filter  $G(z)$ . In fact, the multirate system in Fig. 14(a) is a linear time-invariant (LTI) system if and only if  $\mathbf{G}(z)$  is a pseudocirculant matrix [29]. From (54), it is clear that we have the following relationship between  $[\mathbf{G}(z)]_{ik}$ , the elements of the matrix  $\mathbf{G}(z)$  and the filter  $G(z)$ :

$$z^{-i}G(z) = \sum_{k=0}^{M-1} z^{-k}[\mathbf{G}(z^M)]_{ik}. \quad (55)$$

Moreover, it can be shown [3] that the matrix  $\mathbf{G}(z)$  is paraunitary if and only if the filter  $G(z)$  is an allpass filter. When  $G(z)$  is FIR, this is impossible unless  $G(z)$  is a delay.

**2. Relation of One-Level FB Convolver to Conventional Block Filtering:** In the case of one-level FB convolver with uniform decimation ratios, the  $i$ th Type 2 polyphase component of  $x(n) * g(n)$  can be written as (5) with  $L = M$  and all  $p_k = 1$ . We reproduce the equation here for convenience:

$$\begin{aligned} Y_i(z) &= (z^{-i}X(z)G(z))_{1M} \\ &= \sum_{k=0}^{M-1} X_k(z)G_k^{(i)}(z), \quad 0 \leq i \leq M-1 \end{aligned} \quad (56)$$

where the subband signal  $G_k^{(i)}(z)$  is the  $k$ th GPP component of  $z^{-i}G(z)$  with respect to  $\{H_l(z)\}$  as defined in Fig. 1(b). By writing (56) for all values of  $i$ , we obtain the matrix equation:

$$\begin{pmatrix} Y_0(z) \\ Y_1(z) \\ \vdots \\ Y_{M-1}(z) \end{pmatrix} = \mathbf{G}_{\text{one}}(z)\mathbf{x}(z) \quad (57)$$

where the column vector

$$\mathbf{x}(z) = [X_0(z) \ X_1(z) \ \cdots \ X_{M-1}(z)]^T$$

Fig. 14. Unified view of block filtering and filter bank convolvers: (a) Conventional block filtering; (b) one-level FB convolver; (c) two-level FB convolver.

and the matrix  $\mathbf{G}_{\text{one}}(z)$  is defined as

$$\mathbf{G}_{\text{one}}(z) = \begin{pmatrix} G_0^{(0)}(z) & G_1^{(0)}(z) & \cdots & G_{M-1}^{(0)}(z) \\ G_0^{(1)}(z) & G_1^{(1)}(z) & \cdots & G_{M-1}^{(1)}(z) \\ \vdots & \vdots & \ddots & \vdots \\ G_0^{(M-1)}(z) & G_1^{(M-1)}(z) & \cdots & G_{M-1}^{(M-1)}(z) \end{pmatrix}. \quad (58)$$

By the definition of Type 2 polyphase representation, the output of the convolution  $y(n)$  can be written compactly as

$$\begin{aligned} Y(z) &= \tilde{\mathbf{e}}(z) \begin{pmatrix} Y_0(z^M) \\ Y_1(z^M) \\ \vdots \\ Y_{M-1}(z^M) \end{pmatrix} \\ &= \tilde{\mathbf{e}}(z)\mathbf{G}_{\text{one}}(z^M)\mathbf{x}(z^M) \end{aligned} \quad (59)$$

where  $\tilde{\mathbf{e}}(z)$  is the row vector  $[1 \ z \ \cdots \ z^{M-1}]$ . From (59), we immediately get the implementation in Fig. 14(b), by using the fact that  $X_k(z) = [X(z)H_k(z)]_{1M}$ .

**Comparison Between One-Level FB Convolver and Conventional Block Filtering:** Comparing Fig. 14(a) and (b), we discover that the one-level FB convolver is a generalized version of block filtering. Instead of decomposing  $x(n)$  and  $g(n)$  into their conventional polyphase components as we did in Section VI-A-1, we decompose  $x(n)$  and  $g(n)$  into their GPP components respectively with respect to two separate sets of polyphase basis, namely  $\{H_i(z)\}$  and  $\{F_i(z)\}$ . The

delay chain before the block filter is replaced by a more general analysis bank with filters  $\{H_k(z)\}$ . Therefore, we can view the convolver as a generalized block filtering technique, which provides not only the advantage of parallelism, but also the advantage of coding gain when implemented in finite precision. Of course, the coding gain is obtained at the expense of the cost of one filter bank. This generalized block filtering technique provides a good tradeoff between the coding gain and the complexity. This is the advantage that the conventional block filtering technique does not have. By using GPP representation, a relationship similar to (55) between  $[\mathbf{G}_{\text{one}}(z)]_{ik}$  and  $G(z)$  can be interpreted nicely as

$$z^{-i}G(z) = \sum_{k=0}^{M-1} [\mathbf{G}_{\text{one}}(z^M)]_{ik} H_k(z). \quad (60)$$

It also can be proved (see Appendix B) that the matrix  $\mathbf{G}_{\text{one}}(z)$  is paraunitary if and only if the filter  $G(z)$  is an all-pass function, provided that the set of filters  $\{H_k(z)\}$  is paraunitary.

**3. Relation of Two-Level FB Convolver to Conventional Block Filtering:** For two-level FB convolver with uniform decimation ratios, the  $i$ th GPP component of  $x(n) * g(n)$  with respect to the polyphase basis  $\{F'_i(z)\}$  is

$$Y_i(z) = \sum_{k=0}^{M-1} X_k(z) G_k^{(i)}(z), \quad 0 \leq i \leq M-1, \quad (61)$$

where the subband signals  $G_k^{(i)}(z)$  are the  $k$ th GPP components of  $H'_i(z)G(z)$  with respect to  $\{H_i(z)\}$  as defined in Fig. 2. By writing (61) for all values of  $k$ , we get the equations similar to (57) and (58), except that the matrix  $\mathbf{G}_{\text{one}}(z)$  is replaced by  $\mathbf{G}_{\text{two}}(z)$ , where  $[\mathbf{G}_{\text{two}}(z)]_{ki} = G_k^{(i)}(z)$ . By defining the row vector  $\mathbf{f}'(z) = [F'_0(z) F'_1(z) \cdots F'_{M-1}(z)]$ , the output of the convolution  $y(n)$  can be reconstructed from the GPP components  $Y_i(z)$  (as defined in (61)) as

$$Y(z) = \sum_{k=0}^{M-1} Y_i(z^M) F'_k(z) = \mathbf{f}'(z) \mathbf{G}_{\text{two}}(z^M) \mathbf{x}(z^M) \quad (62)$$

where the column vector  $\mathbf{x}(z)$  is as defined in previous section. From (62), we get the implementation of the two-level FB convolver as in Fig. 14(c).

**Comparison Between One- and Two-Level FB Convolver in the Light of Block Filtering:** Comparing Fig. 14(b) and (c), clearly the two-level FB convolver is a generalized version of one-level FB convolver. In the two-level FB convolver, the "advance chain" in the one-level FB convolver after the block filter is replaced by a more general synthesis bank with filters  $\{F'_i(z)\}$ . Notice that the sets of filters  $\{H_k(z)\}$  and  $\{F'_i(z)\}$  can come from two different biorthogonal systems. The relationship between  $[\mathbf{G}_{\text{two}}(z)]_{ik}$  and  $G(z)$  can be written as

$$H'_i(z)G(z) = \sum_{k=0}^{M-1} [\mathbf{G}_{\text{two}}(z^M)]_{ik} H_k(z). \quad (63)$$

Similarly, we can prove (Appendix B) that the matrix  $\mathbf{G}_{\text{two}}(z)$  is paraunitary if and only if the filter  $G(z)$  is an all-pass function, provided that the sets of filters  $\{H_k(z)\}$  and  $\{H'_k(z)\}$  are paraunitary.

*Remarks:* The adaptive structure in Fig. 2 of [14] is a simplified version of the two-level FB convolver in Fig. 14(c) (with the second set of filter  $F'_k(z)$  replaced with  $F_k(z)$ ).

### B. Aliasing Effects and the Equivalent LPTV Filter in the Presence of Quantizers

In the presence of quantizers in the subband of  $g(n)$ , the equivalent system is not a linear time invariant (LTI) system anymore. We will discuss the aliasing effect and the relation between the subband convolver and a linear periodically time varying (LPTV) system.

Let  $Q_k^{(i)}(z)$  be the  $z$  transform of  $q_k^{(i)}(n)$ , where  $q_k^{(i)}(n)$  is defined in (33). Define the matrix  $\mathbf{Q}(z)$

$$\mathbf{Q}(z) = \begin{pmatrix} Q_0^{(0)}(z) & Q_1^{(0)}(z) & \cdots & Q_{M-1}^{(0)}(z) \\ Q_0^{(1)}(z) & Q_1^{(1)}(z) & \cdots & Q_{M-1}^{(1)}(z) \\ \vdots & \vdots & \ddots & \vdots \\ Q_0^{(M-1)}(z) & Q_1^{(M-1)}(z) & \cdots & Q_{M-1}^{(M-1)}(z) \end{pmatrix}. \quad (64)$$

Let  $\hat{\mathbf{G}}_{\text{one}}(z)$  be the quantized version of  $\mathbf{G}_{\text{one}}(z)$ . Then  $\hat{\mathbf{G}}_{\text{one}}(z) = \mathbf{G}_{\text{one}}(z) + \mathbf{Q}(z)$ . The system in Fig. 14(b) can be drawn equivalently as that in Fig. 15(a). The upper path gives the desired output and the lower path represents the error. By using the polyphase representation, Fig. 15(a) can be redrawn as Fig. 14(b) where

$$\mathbf{P}(z) = \mathbf{Q}(z)\mathbf{E}(z) \quad (65)$$

and  $\mathbf{E}(z)$  is the polyphase matrix of the analysis filters  $H_k(z)$ . From Fig 15, we see that the lower path is an LPTV filter and it is an LTI filter if and only if the matrix  $\mathbf{P}$  is pseudocirculant (see Section 10.1 of [3]). For the case of the two-level FB convolver as in Fig. 14(c), the similar result holds except that the matrix  $\mathbf{P}(z)$  is replaced by

$$\mathbf{P}(z) = \mathbf{R}'(z)\mathbf{Q}(z)\mathbf{E}(z) \quad (66)$$

where  $\mathbf{R}'(z)$  is the Type 2 polyphase matrix of the synthesis filters  $F'_i(z)$ .

Let  $\mathbf{d}(z) = [d_0(z) d_1(z) \cdots d_{M-1}(z)]^T = \mathbf{P}(z^M)\mathbf{e}(z)$ , where  $\mathbf{e}(z) = [1 z^{-1} \cdots z^{-(M-1)}]^T$ , and let  $T_i(z) = z^{-i}G(z) + d_i(z)$ . Then, the system in Fig. 15 can be redrawn as Fig. 7. The aliasing components  $A_i(z)$  (see equation (5.4.7) of [3]) can be expressed as

$$A_i(z) = \frac{1}{M} \sum_{k=0}^{M-1} z^k d_k(zW^i), \quad \text{for } 1 \leq i \leq M-1 \quad (67)$$

and

$$A_0(z) = G(z) + \frac{1}{M} \sum_{k=0}^{M-1} d_k(z). \quad (68)$$

$G(z)$  is the desired response,  $(1/M) \sum_{k=0}^{M-1} d_k(z)$  represents the distortion and for  $1 \leq i \leq M-1$ ,  $A_i(z)$  are the aliasing

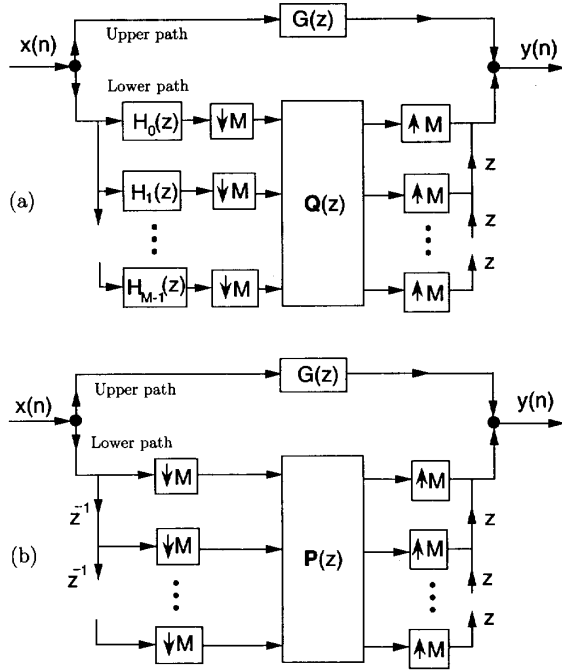

Fig. 15. (a) Equivalent representation of Fig. 6(a); (b) block filter representation.

components. The error due to the aliasing and distortion can be written as

$$\begin{aligned} \varepsilon^2 &= \sum_{i=1}^{M-1} |A_i(e^{j\omega})|^2 + |A_0(e^{j\omega}) - G(e^{j\omega})|^2 \\ &= \sum_{i=0}^{M-1} \left| \frac{1}{M} \sum_{k=0}^{M-1} e^{jk\omega} d_k(e^{j(\omega-2\pi i/M)}) \right|^2 \\ &\leq \frac{1}{M^2} \sum_{i=0}^{M-1} \sum_{k=0}^{M-1} |d_k(e^{j(\omega-2\pi i/M)})|^2. \end{aligned} \quad (69)$$

The magnitude responses of  $d_k(z)$  for Example 1 are shown in Fig. 16. All the magnitude responses are under 40 dB even though the coefficients are quantized to an average bit rate of 4 b only.

### C. Subband Implementation of LPTV Filters

From the earlier discussion in this section, it is natural to ask if the subband convolver can be modified to implement an LPTV filter. In the following we will show that the answer is in the affirmative. The implementation leads to a low sensitivity structure for LPTV filters.

Given an LPTV filter with period  $L$ , we can characterize the filter by a set of  $L$  transfer functions  $\{T_i(z)\}$  as shown in Fig. 7. Notice from the figure that the  $i$ th polyphase component  $y_i(n)$  of the output of the LPTV filter is completely determined by the transfer function  $T_i(z)$ . By Theorem 2.1,  $y_i(n)$  can be

Fig. 16. Magnitude responses of the aliasing components.

obtained as:

$$\begin{aligned} y_i(n) &= (x(n) * t_i(n))_{\downarrow L} \\ &= \sum_{k=0}^{M-1} (x_k(n) * t_{ik}(n))_{\downarrow p_k} \end{aligned} \quad (70)$$

where  $t_i(n)$  is the impulse response of  $T_i(z)$ ,  $x_k(n)$  are defined in Fig. 1(a), and  $t_{ik}(n)$  are the subband signals obtained by replacing  $g(n-i)$  in Fig. 1(b) with  $t_i(n)$ . The periodically time varying bit allocation can be employed to achieve a low sensitivity structure for LPTV filters.

## VII. FB CONVOLVERS FOR LINEAR-PHASE FILTERS

Suppose that  $g(n)$  has linear phase. In the direct form implementation, the symmetry of the impulse response can be exploited to reduce the complexity by one half. Furthermore, the phase remains linear even in the presence of quantization. In the previous discussion, the FB convolvers do not take advantage of the symmetry. In the following, we will see how to preserve the advantages of linear phase and at the same time achieve high coding gain for FB convolvers. Since the method works for orthonormal filter banks only, we will assume that  $\{H_k(z)\}$  and  $\{F_k(z)\}$  are orthonormal. Assume that the length of the filter  $N = jL$ , where  $L$  is the lcm of  $n_k$  shown in Fig. 1. We will derive the case where  $g(n)$  is symmetric with even length (derivations for other cases are very similar).

$$G(z) = \underbrace{\sum_{n=0}^{N/2-1} g(n)z^{-n}}_{\bar{G}(z)} + \underbrace{\sum_{n=N/2}^{N-1} g(n)z^{-n}}_{z^{-N}\bar{G}(z^{-1})}. \quad (71)$$

By using the GPP representation, we decompose  $X(z)$  and  $\bar{G}(z)$ , respectively, as

$$\begin{aligned} X(z) &= \sum_{k=0}^{M-1} X_k(z^{n_k}) F_k(z) \\ &= \sum_{k=0}^{M-1} X'_k(z^{n_k}) H_k(z), \end{aligned} \quad (72a)$$

$$\bar{G}(z) = \sum_{k=0}^{M-1} \bar{G}_k(z^{n_k}) H_k(z). \quad (72b)$$

If the filter bank formed by  $H_k(z)$  and  $F_k(z)$  is orthonormal so that  $H_k(z^{-1}) = F_k(z)$ , then we can write

$$z^{-N}\bar{G}(z^{-1}) = \sum_{k=0}^{M-1} z^{-N}\bar{G}_k(z^{-n_k})F_k(z). \quad (73)$$

By using the relations in (71)–(73), the decimated output of the convolution  $x(n) * g(n)$  can be written as

$$\begin{aligned} [G(z)X(z)]_{\downarrow L} &= \left[ \sum_{k=0}^{M-1} \sum_{i=0}^{M-1} \bar{G}_k(z^{n_k})X_i(z^{n_i})H_k(z)F_i(z) \right]_{\downarrow L} \\ &+ \left[ \sum_{k=0}^{M-1} \sum_{i=0}^{M-1} z^{-N}\bar{G}_k(z^{-n_k}) \right. \\ &\quad \left. \cdot X'_i(z^{n_i})F_k(z)H_i(z) \right]_{\downarrow L} \\ &= \sum_{k=0}^{M-1} (\bar{G}_k(z)X_k(z))_{\downarrow p_k} \\ &+ z^{-j} \sum_{k=0}^{M-1} (\bar{G}_k(z^{-1})X'_k(z))_{\downarrow p_k} \end{aligned} \quad (74)$$

where  $p_k = L/n_k$ . Since  $\bar{G}_k(z)$  and  $\bar{G}_k(z^{-1})$  are time-reversed versions of each other, their multipliers can be shared. We have successfully reduced the complexity to one half and preserved the phase linearity of the overall filter even in the presence of quantizers. However the implementation in (74) may not give high coding gain because in general the filter  $\bar{G}(z)$  is not frequency selective due to the artificial discontinuity introduced by truncation. A technique was proposed in [23] to solve this problem. Instead of partitioning  $G(z)$  in a non overlapping manner as in (71), if we allow some small overlapping in the partition (which would introduce some computational overhead), then it was shown in [23] that good coding gain can be achieved by using a raised-cosine function to shape the overlapping region. Therefore there is a tradeoff between the complexity and the coding gain. Experiments [23] showed that an overlap of less than 10 taps will provide high coding gain.

## VIII. CONCLUDING REMARKS

### A. IFIR Filter as a Special Case of Subband Convolver

IFIR filters were introduced in [15] to design narrowband filters. In lowpass case, if the stopband edge is smaller than  $\pi/M$ , then  $G(z)$  can be approximated by a cascade of two filters as:

$$G(z) \approx G^{(0)}(z^M)I(z) \quad (75)$$

where  $I(z)$  is a low cost filter. The number of coefficients in  $G^{(0)}(z)$  is roughly equal to  $1/M$  of that in  $G(z)$ . Fig. 17(a) shows the implementation of an IFIR filter.

From Fig. 1(b),  $G(z)$  can be decomposed into its GPP components as

$$G(z) = \sum_{k=0}^{M-1} G_k^{(0)}(z^M)H_k(z). \quad (76)$$

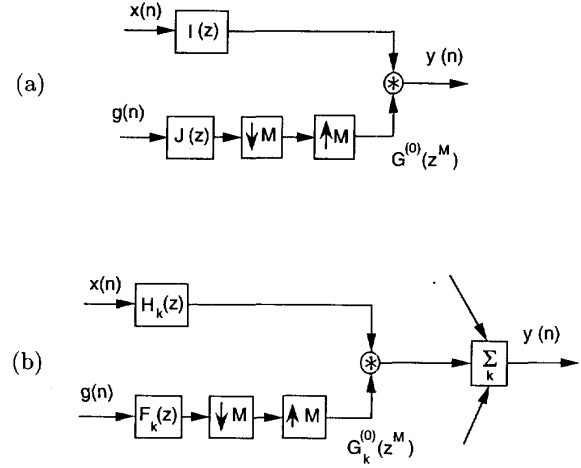

Fig. 17. Relationship between convolver and IFIR filter: (a) Implementation of IFIR filter; (b) implementation of convolver.

The decomposition is exact. Fig. 17(b) shows the implementation. If  $G(z)$  has pass-band smaller than  $\pi/M$ , then only  $G_0^{(0)}(z)$  in (76) has significant energy. By dropping all the other unimportant channels in Fig. 17(b) corresponding to  $G_k^{(0)}(z)$  ( $k = 1, 2, \dots, M-1$ ), Fig. 17(b) reduces to Fig. 17(a) (with  $H_0(z)$  and  $F_0(z)$  regarded as  $I(z)$  and  $J(z)$ , respectively). Therefore, more generally, if  $G(z)$  is a multi-band filter, the subband convolver can be used to approximate  $G(z)$  by retaining the channels which contain most of the energy.

### B. Low-Sensitivity Structures for IIR Filters

The application of the FB convolvers in the implementation of IIR filters is not very useful for the following reasons:

- The FB convolver for IIR filters involves the implementation of an LPTV system in the feedback loop, and it is very difficult to ensure the stability in the presence of quantizers.
- A causal FB convolver will introduce some delay for the output in the feedback loop and this will make the overall system noncausal.
- IIR filters seldom have an order  $N$  greater than 10, so it is not efficient to implement IIR filters with FB convolvers.

## IX. CONCLUSIONS

In this paper, we have generalized the subband convolution theorem in [2]. We have derived the coding gain for the generalized convolver, and it was proved that this coding gain is always greater than that of the one-level FB convolver in [2]. We also unified the subband convolvers, GPP representation, block filtering, LPTV filters, and IFIR filters under one framework. This framework provides us a better understanding of the subband convolvers. We have also shown that the convolvers are closely related to the conventional block filtering. Both the one- and two-level FB convolvers can be viewed as generalized block filtering. As an application of

the convolution theorem, a low sensitivity structure for FIR filters is proposed. We have defined the deterministic coding gain of the low sensitivity structure and demonstrated that the coding gain is high. Even when the filter coefficients are quantized to a very low bit rate, we can get filters of small passband ripple and large stopband attenuation.

#### APPENDIX A PROOF OF (42)

First, we will prove a fact about vector norms inequality. This will be used to derive (42).

**Fact A.1:** Let  $\mathbf{v} = [v_0 \ v_1 \ \dots \ v_{N-1}]^T$ , and let  $\|\cdot\|_1$  and  $\|\cdot\|_2$  denote 1-norm and 2-norm, respectively. Then,  $\|\mathbf{v}\|_1 \leq \sqrt{N} \|\mathbf{v}\|_2$ .

*Proof:* Let

$$\mathbf{1} = [1 \ 1 \ \dots \ 1]^T$$

and

$$\mathbf{u} = [|v_0| \ |v_1| \ \dots \ |v_{N-1}|]^T.$$

Then, we have

$$\begin{aligned} \|\mathbf{v}\|_1 &= \sum_{i=0}^{N-1} |v_i| = \mathbf{1}^T \cdot \mathbf{u} \\ &\leq \|\mathbf{1}\|_2 \|\mathbf{u}\|_2 = \|\mathbf{1}\|_2 \|\mathbf{v}\|_2 = \sqrt{N} \|\mathbf{v}\|_2, \end{aligned} \quad (\text{A.1})$$

using the Cauchy-Schwarz inequality.  $\square$

By definition, we have

$$\begin{aligned} g_{k,\max} &= \max_{i,n} |g_k^{(i)}(n)| = \max_{i,n} |(g(n-i) * h_k(n))_{1n_k}| \\ &= \max_n |g(n) * h_k(n)| \leq g_{\max} \sum_{n=0}^{L_{H_k}-1} |h_k(n)|. \end{aligned} \quad (\text{A.2})$$

The third equality follows from the fact that  $(g(n-i) * h_k(n))_{1n_k}$  is one of the polyphase components of  $g(n) * h_k(n)$ . The last inequality follows directly from triangular inequality. Applying Fact A.1 and the fact that  $h_k(n)$  has unit energy (2-norm is unity), (42) follows immediately.

#### APPENDIX B PROOF OF SOME FACTS IN BLOCK FILTERING

**Lemma B.1—One-Level FB Convolver:** Suppose that the set of filters  $\{H_k(z)\}$  is paraunitary. Then, the matrix  $\mathbf{G}_{\text{one}}(z)$  defined in Fig. 14(b) is paraunitary if and only if the filter  $G(z)$  is an all-pass function.

*Proof:* By writing (60) for all values of  $i = 0, 1, \dots, M-1$ , we have the following matrix equation:

$$\begin{aligned} \begin{pmatrix} G(z) \\ z^{-1}G(z) \\ \vdots \\ z^{-M+1}G(z) \end{pmatrix} &= \mathbf{G}_{\text{one}}(z^M) \begin{pmatrix} H_0(z) \\ H_1(z) \\ \vdots \\ H_{M-1}(z) \end{pmatrix} \\ &= \mathbf{G}_{\text{one}}(z^M) \mathbf{E}(z^M) \mathbf{e}(z) \end{aligned} \quad (\text{B.1})$$

where the matrix  $\mathbf{E}(z)$  is the polyphase matrix of the filters  $\{H_k(z)\}$  and  $\mathbf{e}(z) = [1 \ z^{-1} \ \dots \ z^{-M+1}]^T$ . Substituting  $z$  with  $zW^{-i}$  for  $i = 0, 1, \dots, M-1$  into the above equation, we get

$$\mathbf{A}(z) \mathbf{W} \Phi_G(z) = \mathbf{G}_{\text{one}}(z^M) \mathbf{E}(z^M) \mathbf{A}(z) \mathbf{W} \quad (\text{B.2})$$

where  $\mathbf{A}(z)$  is the diagonal matrix

$$\begin{aligned} &\text{diag}[1 \ z^{-1} \ \dots \ z^{-M+1}], \Phi_G(z) \\ &= \text{diag}[G(z) \ G(zW) \ \dots \ G(zW^{M-1})] \end{aligned}$$

and  $\mathbf{W}$  is the  $M \times M$  DFT matrix with  $[\mathbf{W}]_{ki} = W^{ki}$ . Since  $\mathbf{A}(z)$ ,  $\mathbf{W}$  and  $\mathbf{E}(z)$  are paraunitary matrices,  $\mathbf{G}_{\text{one}}(z)$  is paraunitary if and only if  $\Phi_G(z)$  is. The proof is complete.  $\square$

**Lemma B.2—Two-Level FB Convolver:** Suppose that the sets of filters  $\{H_k(z)\}$  and  $\{H'_k(z)\}$  are paraunitary. Then the matrix  $\mathbf{G}_{\text{two}}(z)$  defined in Section VI-A-3 (Fig. 14(c)) is paraunitary if and only if the filter  $G(z)$  is an all-pass function.

*Proof:* The proof is similar to that of Lemma B.1. By using (63) and following the procedure in the proof above, the lemma follows.  $\square$

**P. P. Vaidyanathan** (S'80-M'83-SM'88-F'91) received the B.Sc. (Hons.) degree in physics and the B. Tech. and M. Tech. degrees in radiophysics and electronics, all from the University of Calcutta, India, in 1974, 1977, and 1979, respectively, and the Ph. D degree in electrical and computer engineering from the University of California at Santa Barbara in 1982.

He was a postdoctoral fellow at the University of California, Santa Barbara, from September 1982 to March 1983. In March 1983, he joined the electrical engineering department of the California Institute of Technology as an Assistant Professor, and since 1993, he has been Professor of electrical engineering there. His main research interests are in digital signal processing, multirate systems, wavelet transforms, and adaptive filtering.

Dr. Vaidyanathan served as Vice-Chairman of the Technical Program committee for the 1983 IEEE International Symposium on Circuits and Systems and as the Technical Program Chairman for the 1992 IEEE International Symposium on Circuits and Systems. He was an Associate Editor for the IEEE TRANSACTIONS ON CIRCUITS AND SYSTEMS for the period 1985–1987 and is currently an associate editor for the IEEE SIGNAL PROCESSING LETTERS. He is also a consulting editor for the journal *Applied and Computational Harmonic Analysis*. He has authored a number of papers in IEEE journals and is the author of the book *Multirate Systems and Filter Banks*. He has written several chapters for various signal processing handbooks. He was a recipient of the Award for excellence in teaching at the California Institute of Technology for the years 1983–1984, 1992–93, and 1993–94. He also received the NSF's Presidential Young Investigator award in 1986. In 1989, he received the IEEE ASSP Senior Award for his paper on multirate perfect-reconstruction filter banks. In 1990, he was recipient of the S. K. Mitra Memorial Award from the Institute of Electronics and Telecommunications Engineers, India, for his joint paper in the IETE journal. He was also the coauthor of a paper on linear-phase perfect reconstruction filter banks in the IEEE TRANSACTIONS ON SIGNAL PROCESSING, for which the first author (T. Nguyen) received the *Young Outstanding Author* award in 1993.

**See-May Phoong** (S'93) received the B.S. degree in electrical engineering from the National Taiwan University, Taipei, Taiwan, in 1991 and the M. S. degree in electrical engineering from the California Institute of Technology in 1992. He is currently pursuing the doctoral degree at the California Institute of Technology.

His interests include digital signal processing, multirate filter banks, and wavelet transforms.
